Title: The effects of spring freezing events on temperate forests and agricultural crops in a changing climate

Study Interests and Aims: I am interested the effects of late spring freezing events, known as false springs, on forest and agricultural systems around the United States. These events are currently predicted to become more intense and widespread as climate change progresses. False spring events are widely documented to result in highly adverse ecological and economic consequences, and with a changing climate, our ability to accurately forecast these events has become more critical.

Research Questions: Temperate forest trees and temperate crops have evolved a myriad of avoidance and tolerance strategies in order to minimize the effects of false spring events but each species will respond differently to climate change. The major goals of my graduate studies are to determine the interspecific variation of false spring damage across various temperate tree species through experimental work and to target regions most at risk of false spring damage through models and meta-analysis. I also plan to work with saplings in the field to evaluate the effects of false springs on life stage, which is necessary to understand the long-term sustainability of our forests.

Background, Goals and Relevance: I have worked alongside conservation management teams at five different reserves in southern Africa and have assisted in various conservation efforts around Dublin, Ireland. In 2015, I earned an M.Sc degree in Biodiversity and Conservation at Trinity College Dublin. For my thesis, I spent two months in Mozambique, investigating the impact of humans on herbaceous species and consequently the effects on herbivores. Many of the issues involved in my master's thesis investigated the interplay between humans and wildlife, which made me realize the importance of incorporating economics, policy, and the public in ecological studies. My career and personal aspirations are to work for a US nonprofit or governmental organization that integrates these key factors into climate change mitigation regimes. It is now essential for researchers to actively pursue climate change research and to implement effective conservation programs to effectively minimize the adverse effects of raising atmospheric CO₂.

Forest ecosystems are crucial carbon sinks that help alleviate the detrimental effects of raising atmospheric CO₂ and they must be protected. False spring events could pose a threat to future forest ecosystems and our crops. Researchers must implement a more thorough approach with false spring studies to accurately predict future trends. Forests provide numerous resources for infrastructure, the military, business organizations, and the economy and agricultural systems are essential to feed the American people with nutritious, home-grown crops. My aims are to work towards finding a solution and help protect our natural environment, food supply, and economy.
